In this sixth and last session we see the use of `Generics`, error handling at run time with `Exceptions`, *inner classes* and `Streams`.

We start with `Generics`: we use this feature when we don't want to specify the type of a field of a class, or the type returned by a method, controlling at the same time that the type remains unchanged for a specific instantiation of the class. This last requirement is the reason why we don't simply declare the type of the field, or the returning type of the method, to be `Object`, which is the largest class from which every other class inherits: in this last case, for one object we can set the type of the `Object` type field to be first `Integer` and then `Double`. If we want to prevent this behaviour, `Generics` is the right tool.

The code in the package

<div align="center">

`com.andreamazzon.session6.generics.containers`

</div>

provides a first example of the syntax and use of `generics`: `GenericClass<T>` is a `generic` class with a field `T genericField` whose type is not specified when we define the class, but has to be the same for a specific instance of `GenericClass<T>`. Here `T` placed inside angular brackets is a placeholder for the type of `genericField`: if we want to create an object `newObject` for which `genericField` has type `Double` we write

<div align="center">

`GenericClass<Double> newObject = GenericClass<Double>`.

</div>

Another application can be seen in the packages

<div align="center">

`com.andreamazzon.session6.generics.genericinterfaces`,

</div>

where a `generic` interface `GenericNext` is defined with a method `next()` which returns an object of type not specified, but same for every object calling that method,

<div align="center">

`com.andreamazzon.session6.generics.fibonacci`,

</div>

and

<div align="center">

`com.andreamazzon.session6.generics.readstring`,

</div>

where two classes implementing `GenericPointer` are defined, one for which `next()` returns an `Integer` and one for which `next()` returns a `Character`.

The second topic is run time error handling with `exceptions`: Java exception handling is a way to guarantee that a run time error is noticed, and that something happens as a result. In particular, an `exception` is an object that is *thrown* from the site of the error and can be *caught* by an appropriate exception handler designed to handle that particular type of error. When you throw an `exception`, two main things happen. First, the `exception` object is created in the same way that any Java object is created: on the heap, with `new`. Then the current path of execution (the one you could not continue) is stopped and the reference of the exception object is ejected from the current context.

We see two examples: the first one, contained in

<div align="center">

`com.andreamazzon.session6.exceptions.commonexception`,

</div>

shows a typical `exception` automatically thrown by Java, i.e., `ArrayIndexOutOfBoundsException`. As it is the case for other `exceptions` automatically thrown by Java, you don't need to write an `exception` specification saying that a method might throw such an `exception`: they are so common that if you had to do so, your code would have been too messy.

On the other side, in

<div align="center">

`com.andreamazzon.session6.exceptions.divisions`

</div>

we see how to `throw` and `catch` some `exceptions` that we write ourselves: these are classes extending the class `Exception`, and when they are *thrown* we create new objects of these classes. In our example, when they are *catched*, we ask these objects to call methods where we print the type of the error.

As a next topic, we have a look at *inner classes*: these are classes defined inside another class, exactly as we usually do. In particular, in

<div align="center">

`com.andreamazzon.session6.innerclasses.innerouteraccess`

</div>

we see a first example of an inner class, and how private fields of the outer class can be accessed from the inner class and vice versa. We note that an object of the inner class must keep a reference to the particular object of the enclosing class that was responsible for creating it (and we see how).

This is not true for *nested classes*, that are `static` inner classes, meaning that you don't need an outer-class object in order to create an object of the nested class, so that the object of the nested class does not keep a reference to any object of the enclosing class. We see such an example in

<div align="center">

`com.andreamazzon.session6.innerclasses.nestedclasses`.

</div>

Inner classes are the only classes that can be made `private`: as we show in

<div align="center">

`com.andreamazzon.session6.innerclasses.privateinnerclasses`,

</div>

the creation of objects of `private` classes is possible only from inside the class where they defined. Here the `private` inner class `MessagePrinter` of `Message` implements an interface `Printer`. When an object of such a class is created in `Message` by calling the `public getAPrinter()` method, it is attached to a reference of type `Message`, and in this way everything not regarding the methods of the interface is hidden to the user.

In the package

<div align="center">

`com.andreamazzon.session6.innerclasses.anonymusinnerclasses`

</div>

we have a look at how *anonymous* inner classes can be defined inside a class. In our case, the *anonymous* inner class defined inside the class `Letter` implements the interface `Envelope`.

Finally, in the class

<div align="center">

`com.andreamazzon.session6.streams.StreamsExample`

</div>

we have a brief look at the use of `streams`: in particular, we see how the use of this tool makes our life considerably easier when we want to perform some operations with data sets that would require more time and more lines of code using `arrays` or `lists`.
